Drinking water companies more and more implement Advanced Oxidation Processes (AOP) in their treatment schemes to increase the barrier against organic micropollutants (OMPs). It is necessary to decompose the excessive hydrogen peroxide after applying AOP to avoid negative effects in the following, often biological, treatment steps. A drinking water company in the western part of the Netherlands investigated decomposition of about 5.75 mg L<sup>-1</sup> hydrogen peroxide in pre-treated Meuse river water with different catalysts on pilot scale.

In down flow operation, the necessary reactor Empty Bed Contact Time (EBCT) with the commonly used Granulated Activated Carbon (GAC) and waste ground water filter gravel (MCFgw) were the same with 149 s, corresponding with a conversion rate constant r of 0.021 s<sup>-1</sup>. The EBCT of the fine coating of ground water filter gravel (MC) was significantly shorter with a little more than 10 s ( $r = 0.30 \, s^{-1}$ ).

In up flow operation, with a flow rate of  $20 \,\mathrm{m\,h^{-1}}$ , the EBCT of coating MC increased till about  $100 \,\mathrm{s}$  ( $r = 0.031 \,\mathrm{s^{-1}}$ ), from which can be concluded, that the performance of this waste material is better compared with GAC, in both up and down flow operation.

The necessary EBCT at average filtration rate of full scale dual layer filter material (MCFsw) amounted to  $209 \, \mathrm{s} \ (r = 0.015 \, \mathrm{s}^{-1})$ . Regarding the average residence time in the full scale filters of  $700 \, \mathrm{s}$ , applying AOP in front of the filters could be an interesting alternative which makes a separate decomposition installation superfluous, on the condition that the primary functions of the filters are not affected.

#### 1 Introduction

All over the world surface water is to some extend contaminated with organic micropollutants (OMPs). It is expected that the amount and concentrations of OMPs will increase, due to population growth, aging and global warming. A drinking water company in the western part of the Netherlands identified the threat of OMPs in their source the

Discussion Paper

Afgedamde Maas, a side branch of the Meuse river. The managed aquifer recharge (MAR) by dune filtration and the dosing of powdered activated carbon (PAC) are currently the main barriers against OMPs. After careful consideration advanced oxidation process (AOP) was selected as the most optimal technique to extend the treatment scheme (Abrahamse et al., 2007) and research was carried out with ozone and UV based AOP, in combination with hydrogen peroxide. When AOP is installed before MAR it is expected that this two processes will provide a synergistic, hybrid system (Lekkerker-Teunissen et al., 2012).

A drawback of applying AOP is the remaining hydrogen peroxide in the treated water. After dosing 6 mg L $^{-1}$  hydrogen peroxide in the AOP influent water, about 5.75 mg L $^{-1}$  hydrogen peroxide is remaining in the AOP effluent water. This AOP effluent water flows out in infiltration ponds which recharge the dunes. It is established that even a concentration of 2 mg L $^{-1}$  affects about 80 % of the organisms in the infiltration ponds (Reeze et al., 2010). Because the infiltration ponds are situated in a protected nature area (Natura 2000), it is of utmost importance to lower the hydrogen peroxide concentration till a level that will not affect the ecology. As a company standard, the maximum allowed concentration of hydrogen peroxide in the infiltrated water is established at 0.25 mg L $^{-1}$ .

Hydrogen peroxide in water has a tendency to decompose in water and oxygen, because the reaction products are more stable than the hydrogen peroxide itself (Petrucci et al., 2007):

$$2H_2O_2 \rightarrow 2H_2O + O_2$$
  
 $\Sigma \mu^{\odot} [kG] 2 \cdot (-134.1) \rightarrow 2 \cdot (-237.2) + 0.0$ 

Overall the chemical drive of this so-called decomposition reaction is 206.2 kG. However, the decomposition is very slow, the reason why hydrogen peroxide solutions are commercially available. Decomposition is strongly affected by light and catalysts as catalase, (spores of) metal oxides and activated carbon. In full-scale application, homogeneous catalysis (enzymatic with for example catalase or iron) is not practical. The most promising technique is therefore heterogeneous catalysis. Common catalysts in-

Interactive Discussion

clude manganese oxide, silver, platinum and activated carbon. The surface of these catalysts provides a favorable environment to catalyze the decomposition, though the mechanism is not well understood. Apparently the reaction rate is increased as this alternative route has a lower activation energy than without the catalyst (Masel, 2001). Decomposition starts with adsorption of hydrogen peroxide on the catalyst. The rate of adsorption, and with that the decomposition rate, is higher at higher water temperature and with a larger catalyst surface.

Filtration over granulated activated carbon (GAC) is a proven technology to decompose hydrogen peroxide (Kruithof et al., 2007). The decomposition reaction with pure manganese dioxide in granular form is slow and time demanding (Bazri, 2010). However, it was known that dissolved manganese in surface and groundwater deposits as manganese oxide compounds on grains in sand filters. Microscopic examination vielded promising results: at pre-treatment plant, (oxygen)bubbles were formed at the surface of grains of a full-scale double layer sand filter after adding 1 % hydrogen per-15 oxide solution.

This research focused on the decomposition of about 5 and 10 mg L<sup>-1</sup> hydrogen peroxide till 0.25 mg L<sup>-1</sup> in the pilot plant installation. Three different catalysts were investigated: commonly applied GAC and two types of manganese coated filter material. The main parameter determined for the three decomposing materials was the reactor empty bed contact time (EBCT), based on the conversion rate of the decomposition.

#### Materials and methods

#### Column reactors

Catalytic decomposition was investigated in vertical column reactors, with outside diameters of 0.20, 0.40 and 0.60 m, called R20, R40 and R60, respectively. Sample points over the height of the columns made it possible to analyse the hydrogen peroxide after different contact times.

The two reactors R60 were fed with pre-treated Meuse river water, abstracted before the full-scale double layer sand filters. The reactors R20 and R40 were fed with the effluent of these full-scale double layer sand filters. The flow through the reactors could be varied between 1.0 and  $3.0\,\mathrm{m}^3\,h^{-1}$ , which corresponds with flow rates between 4 and  $100\,\mathrm{m}\,h^{-1}$ . The standard operation was down flow, but up flow operation also was applied with flow rates up till  $40\,\mathrm{m}\,h^{-1}$ . Before the water flowed in the reactors,  $10\,\%$  hydrogen peroxide was dosed into the water with a membrane pump with a maximum capacity of  $3.0\,\mathrm{L}\,h^{-1}$ . The applied concentrations were about 5 and  $10\,\mathrm{mg}\,L^{-1}$  in the influent water.

#### 2.2 Decomposing material

Three different catalysts were used: GAC and two types of manganese coated filter material.

The GAC type was extruded activated carbon with a diameter of 0.8 mm, especially suitable for catalytic processes. The manganese coated filter material were obtained from two different drinking water treatment facilities. The first material was manganese coated filter material from a groundwater treatment plant (MCFgw), replaced at the end of the filter life time. The second manganese coated filter material was obtained from a surface water treatment plant (MCFsw). The MCFsw was collected from the double layer sand filters.

During the first backwashing of MCFgw, a part of the coating was separated from the grains. This coating (MC) was also used as catalyst. With XRD analysis, besides calcium and iron compounds, the manganese containing compounds ramsdellite and birnessite were detected in MC (Hendrix, 2014). Specifications of the manganese containing materials are shown in Table 1.

The hydrogen peroxide concentration in water was analysed on site with a spectrophotometer. The measurement is based on the reaction of hydrogen peroxide with titanium(IV)oxysulphate solution, following DIN 38409 H15. Samples were collected and measured in a volumetric flask, after adding 5.0 ML of the titanium(IV)oxysulphate solution by a pipette. When higher concentrations were expected than  $6 \, \text{mg L}^{-1}$ , the samples were diluted with milli-q water. The samples were measured at a wavelength of 420 nm and corrected for background absorbance, which were determined by analysing the samples without the addition of titanium(IV)oxysulphate solution. At a hydrogen peroxide concentration of  $5.8 \, \text{mg L}^{-1}$  the standard deviation  $\sigma$  was  $0.02 \, \text{mg L}^{-1}$ .

#### 3 Results and discussion

#### 3.1 Activated carbon

With GAC, 5 mg L<sup>-1</sup> hydrogen peroxide was decomposed completely in just more than 120 s empty bed contact time (EBCT), see Fig. 1. In the same EBCT, 10 mg L<sup>-1</sup> hydrogen peroxide was decomposed for about 90 %. This experiment confirmed that activated carbon is well-functioning catalyst for decomposing hydrogen peroxide, even at the low water temperature of 1.8 °C.

#### 3.2 Manganese coated filter material

The decomposition of 5 mg L<sup>-1</sup> hydrogen peroxide with anthracite and gravel MCFsw is plotted in Fig. 2.

In about 250 till 350 s the hydrogen peroxide in both reactors was decomposed completely. The EBCT of the 0.25 m anthracite layer was about 200 s, which means that the anthracite had a major contribution to the decomposition. The total EBCT of 700 s of the 0.85 m bed layer was the same as the average EBCT in the full scale filters, which

Interactive Discussion

means that at least 400 s EBCT remains for the primary functions of the rapid sand filters (removal of iron and manganese, nitrification and mineralization). This observation confirms that applying AOP in front of the rapid sand filters can be an interesting option in practice and could make a separate decomposing installation superfluous, provided that the primary filter functions are not disturbed.

 $10 \,\mathrm{mg} \,\mathrm{L}^{-1}$  (Fig. 3).

A dose of 5 mg L<sup>-1</sup> hydrogen peroxide was completely decomposed in an EBCT of 180 s. A dose of 10 mg L<sup>-1</sup> was decomposed in 260 s. Despite the manganese content of MCFgw of 14 g kg<sup>-1</sup>, about 100 times higher compared to MCFsw, the difference in the decomposing time between MCFgw and MCFsw was no more than 30 %.

The results of decomposition with the fine coating MC was investigated with a dose of 5 mg L<sup>-1</sup> hydrogen peroxide and printed in Fig. 4.

Already within 10 s 95 % of the hydrogen peroxide was decomposed. Clearly the coating with a relatively high manganese content of 100 g kg<sup>-1</sup> had a positive effect on the rate constant of decomposing hydrogen peroxide, conform literature (Bazri, 2010). In addition, the small particles (Table 1) form a large catalyst surface.

Decomposition of hydrogen peroxide is a first order reaction in a heterogeneous environment. Because the reaction does not take place under homogenous circumstances, the decomposition rate is not expressed in a reaction rate constant, but in the conversion rate constant r (Coulson and Richardson, 1996). The conversion rate constant is not only depending of temperature and pressure (as in homogeneous milieu), but also on contact surface of the catalyst and hydraulic conditions in the reactor. In case of a first order reaction, a linear relation exist between the negative natural logarithm of the quotient of the effluent hydrogen peroxide C and influent concentration  $C_0$  and the reaction time  $(-\ln C/C_0 \text{ vs. } t)$ . The relations of the different investigated catalysts are printed in Fig. 5.

The slope of the lines is the value of r. MC had the highest conversion rate constant (note that the value of r is only based on one sample point, because the water in the

Decomposing with the coarse gravel MCFgw was investigated with a dose of 5 and

second sample point did not contain hydrogen peroxide anymore) and much higher compared to the other catalysts. In addition, the conversion rate of the same catalyst depended on the initial hydrogen peroxide concentration. This observation is reported earlier under heterogeneous conditions by Coulson and Richardson (1996).

In Table 2 the necessary EBCT is calculated for the investigated catalysts with an initial concentration  $C_0 = 5.75\,\mathrm{mg\,L}^{-1}$  (corresponding to a dose in the AOP influent of  $6\,\mathrm{mg\,L}^{-1}$ ) and an effluent concentration  $C = 0.25\,\mathrm{mg\,L}^{-1}$  (the allowed concentration in the infiltration ponds), which means that  $\ln C_0/C = 3.135$  and t = 3.135/r. Here, it was assumed that the calculated conversion rate constants at about  $5.0\,\mathrm{mg\,L}^{-1}$  hydrogen peroxide will not differ much from the conversion rate at  $5.75\,\mathrm{mg\,L}^{-1}$ .

The necessary EBCT in the full scale dual layer filters (MCFsw) amounts about 200 s. The EBCTs of GAC and MCFgw equals about 150 s. The EBCT of MC is much lower with approximately 10 s. All experiments were carried out in down flow operation. For full scale operation, however, down flow operation over fine material has the disadvantage of fast clogging of filter material with suspended particles and potential increase of the resistance due to oxygen bubble formation, depending of the oxygen saturation degree of the water. These disadvantages could be solved by up flow operation.

Up flow operation of the coating MC was investigated using three different flow rates. A flow velocity of  $40\,\mathrm{m\,h}^{-1}$  appeared to be the maximum velocity, without carrying the coatings with the effluent of the reactor. The coatings became in fluidised state at a flow velocity of  $4\,\mathrm{m\,h}^{-1}$ . The decomposition of  $5.8\,\mathrm{mg\,L}^{-1}$  hydrogen peroxide is plotted in Fig. 6.

From Fig. 6 it was concluded, that the decomposition was sufficient, which means  $\ln C_0/C \geq 3.135$ , with up flow velocities of 10 and  $20\,\mathrm{m\,h}^{-1}$ . The necessary EBCT was approximately 100 s. At a velocity of  $40\,\mathrm{m\,h}^{-1}$  the decomposition goal could not be achieved. Presumably, the adsorption of hydrogen peroxide on the catalyst was inadequate due to the increased expansion, see Fig. 7, which resulted in less catalyst surface in the same reactor height.

In one way or another pelleting MC till a diameter of about 2 mm would make higher flow velocities possible, and with that a smaller reactor footprint. However, changing the diameter or the surface area of the catalyst or the hydraulic conditions in the reactor, will have impact on the value of the conversion rate constant and consequentially on the design criteria. In addition, the decomposition of hydrogen peroxide depends on the water temperature and will be faster with increasing water temperature. This is visible in Fig. 8, wherein the decomposition is plotted of experiments with GAC at 1.8 °C and 10.7 °C. The concentration of hydrogen peroxide was always lower after the same contact time at a higher water temperature.

#### 4 Conclusions

In down flow operation, the necessary EBCT to decompose  $5.75 \,\mathrm{mg}\,\mathrm{L}^{-1}$  hydrogen peroxide in pre-treated Meuse river water with the commonly used GAC and waste groundwater filter gravel (MCFgw) were the same with about  $150 \,\mathrm{s}$ , corresponding to a conversion rate constant r of  $0.021 \,\mathrm{s}^{-1}$ . The EBCT of the coating of groundwater filter gravel (MC) was much shorter with a little more than  $10 \,\mathrm{s}$  ( $r = 0.30 \,\mathrm{s}^{-1}$ ).

MC was suitable for up flow operation till a flow velocity of about  $20 \,\mathrm{m\,h}^{-1}$ . The necessary EBCT was about  $100 \,\mathrm{s}$  ( $r = 0.031 \,\mathrm{s}^{-1}$ ). At an up flow rate of  $40 \,\mathrm{m\,h}^{-1}$  the decomposition goal could not be achieved, probably due to the increased porosity in the fluidized bed. Pelleting MC till a diameter of about  $2 \,\mathrm{mm}$  would make higher up flow velocities possible.

The necessary EBCT at average filtration velocity of dual layer filter material (MCFsw) amounted to about  $200 \, \text{s} \ (r = 0.015 \, \text{s}^{-1})$ . Regarding the average residence time in the full scale filters of  $700 \, \text{s}$ , applying AOP in front of the filters could be an interesting alternative making a separate decomposition installation superfluous, on the condition that the primary functions of the filters are not affected.
