6

7 **Abstract.** Shock chlorination is a well-known practice in swimming pools and domestic wells. One of the limitations
8 for using this technique in drinking water purification facilities is the difficulty of quickly removing high chlorine
9 concentrations in water distribution systems or production facilities. In order to use this method in the drinking water
10 industry a shock de-chlorination method should be introduced for producing microorganism and biocide free water.
11 De-chlorination using natural stagnant aeration (leaving the water to lose the chlorine naturally) is the safest known
12 method if compared with chemical and charcoaling methods. Unfortunately, stagnant aeration is a slow process.
13 Therefore, developing a process for accelerating de-chlorination by aeration would pave the way for using shock de-
14 chlorination in drinking water industry.

15
16 Forced air bubbling is a possible technique for de-chlorination but there is lack of data supporting such a process. The
17 theory is that air bubbling has the advantages of higher mass transfer area, higher Reynolds number across the bubble
18 water interface, and higher mass transfer concentration gradient as the bubbling presents a continuous stream of fresh
19 bubbles. All of these factors accelerate aeration to various extents.

20
21 A 20 cm diameter, 1-meter height column provided with air sparger was designed to collect the desired data used in
22 this study. Trichloroisocyanuric acid, sodium hypochlorite and chlorine gas were the three familiar sources of chlorine
23 used to investigate their response to air bubbling.

24
25 Chlorine gas was the fastest and safest chlorine source to be dechlorinated. It dropped from 200 ppm to 0.02 ppm
26 within 4 minutes or zero ppm within 6 minutes using an air flowrate of 9 l/min.

27
28 Sodium hypochlorite decreased from 200 ppm to 0.02 ppm within 6 minutes using air flowrate of 9 l/min.
29 Trichloroisocyanuric acid found to be the chlorine source slowest to respond to de-chlorination. It decreased from 200
30 ppm to 0.02 ppm within 8 minutes using an air flowrate of 9 l/min.

31
32 Shock de-chlorination by aeration is found to be a promising method that opens up the drinking water industry and
33 could produce microorganism and biocide free drinking water.

34 **1 Introduction**

35
36 Chlorination of drinking water has been used as a disinfection technique for more than a century or so to produce
37 water that is safe from waterborne diseases. This method is preferred due to low cost, abundance, ease of use and less
38 need of high technology equipment. On the other hand, during the last forty years disinfectant by-products “DBPs” as
39 a new branch of study in the water industry has developed first by discovering the presence of Chloroform (Rook,
40 1974) and trihalomethanes “THMs” (Singer, 1994) in drinking water. To date some 700 or more DBPs have been
41 identified but understanding their effect on humans and the environment still needs more work (Brown et al.,
42 2011;Gonsior et al., 2014;Richardson and Postigo, 2015).

43 Liberating the drinking water industry from chlorination side effects has been approached by developing new
44 chemical, physical and hybrid techniques rather than novel methods such as plasma and solar disinfection (Kumar and
45 Pandit, 2012). All of these strategies imply economical and health disadvantages which still gives disinfection by
46 chlorine an acceptable reason for use in many places around the world.

47 One of the major advantages of chlorine is preventing bacterial regrowth if some residual level is maintained along
48 the distribution system. Recently, some European water treatment factories prevented the regrowth; i.e. producing

49 biologically stable drinking water, by optimizing nutrition levels in effluent water using pretreatment techniques such
 50 as sedimentation, filtration, UV disinfection, ozone, and peroxide (Lautenschlager et al., 2013; Simoes and Simoes,
 51 2013).

52 Shock chlorination is a well-known disinfection process normally used in swimming pools, springs and wells. In all
 53 these applications the water reservoir is kept without use for a certain time for natural de-chlorination. The
 54 concentration of chlorine and contact time for killing all or most of the contaminants varies depending on initial and
 55 desired microorganism concentration and the chemical nature of water that may interfere with the chlorination process
 56 (LeChevallier et al., 1981; Virto et al., 2004; Virto et al., 2005; Helbling and Vanbriesen, 2007). The rare information
 57 about time-concentration needed may be due to the wide nature of reservoirs that make any generalized study difficult.
 58 Furthermore, it is easy to estimate the parameters in simple laboratory experiments. De-chlorination of water by
 59 aeration is also a well-known process but it driven naturally by leaving water in an open vessel for about 24 hours.
 60 This process is used mainly for domestic needs such as de-chlorinating water for fish aquariums. In such applications
 61 the time is available and the amount of water is small. In such cases there is no serious need for forcing the
 62 dechlorination.

63 Contemporary drinking water production and distribution systems should be as biocide and microorganism free as
 64 possible without forgetting the economical aspect. The need for residual biocide for preventing regrowth is decreased
 65 with the development of new techniques (Lautenschlager et al., 2013; Simoes and Simoes, 2013). Therefore, the idea
 66 of shock chlorinating and de-chlorinating potable water may be an acceptable approach for producing high quality
 67 drinking water.

68 In this study the ability of pumped air for de-chlorinating drinking water was investigated. Such information is needed
 69 for the process design of drinking water facilities. The information should help in calculating the dimensions and
 70 operating conditions of continuous chlorination and de-chlorination equipment.

71 **2 Hypothesis**

72 According to Fick's law:

$$73 \quad J = -D \frac{\partial C}{\partial x} \quad (1)$$

74 Where:

75 J: is the diffusion flux ($\frac{mole}{m^2 \cdot s}$)

76 D: is the diffusion coefficient ($\frac{m^2}{s}$)

77 C: is the concentration gradient ($\frac{mol}{m^3}$)

78 x: is the length vertical to m^2 in D and C above (m)

79 (Li et al., 1965) rearrange equation (1) dimensionally to get:

$$80 \quad \frac{dn}{dt} = k_L a(dC) \quad (2)$$

81 Where:

82 n: is the moles of gas transferred (mole)

83 t: is the time (s)

84 k_L : is the mass transfer coefficient (m/s)

85 a: is the mass transfer area (m^2)

86 Therefore, to increase the moles of chlorine transferred, both of mass transfer area (a) and the concentration gradient
 87 (dC) should be increased. Forced aeration is suggested to increase them both.

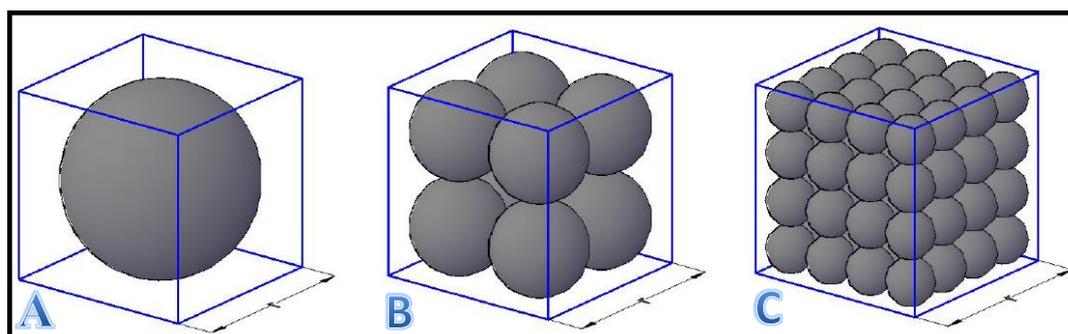

88 **2.1 The role of aeration in increasing the mass transfer area**

89 Chlorine is transferred from water to air through a contact area between air and water. In stagnant aeration the chlorine
 90 is only transferred from the upper surface of the water. Increasing the air water interface will increase chlorine transfer
 91 and decrease the time to reach the desired level of dechlorination.

92 Consider a cube of water with dissolved chlorine of a length of (r).

93 Assume that the upper face of the cube is the mass transfer area for chlorine; which equals to $A=r^2$ as happens in
 94 stagnant aeration.

95 Assume also there is a spherical air bubble of radius (r) inside the cube as in figure (1A). The surface area of this
 96 bubble will be $4\pi r^2$.

97

98

Figure 1: Hypothesis graphical illustration

99 The total surface area available for mass transfer will be the sum of upper face plus the bubble surface areas ($r^2 +$
 100 $4\pi r^2$). The percentage increase in surface area can be expressed as:

101 % surface area increase due to aeration = $\frac{\text{New mass transfer area}}{\text{Original mass transfer area}} \times 100$

102 Or % surface area increase due to aeration = $\left(\frac{r^2 + 4\pi r^2}{r^2} \times 100 \right) = 1357\%$

103 Assume also there are 8 bubbles of a radius ($0.5r$) inside the cube as in figure (1B). The total percentage increase in
 104 surface area will be:

105 % surface area increase due to aeration = $\left(\frac{r^2 + 8(4\pi (0.5r)^2)}{r^2} \times 100 \right) = 2613\%$

106 Finally, assume there are 64 bubbles of radius ($0.25r$) inside the cube as in figure (1C). The total percentage increase
 107 in surface area will be:

108 % surface area increase due to aeration = $\left(\frac{r^2 + 64(4\pi (0.25r)^2)}{r^2} \times 100 \right) = 5127\%$

109 Or in general, % surface area increase due to aeration = $\frac{r^2 + x^3(4\pi(\frac{r}{x})^2)}{r^2} \times 100$

110 Where: x is the number of bubbles that lined adjacently along the length of cube line (r). Or it is the cubic root of the
111 bubbles inside the tubes.

112 Simplifying by eliminating (r) to get:

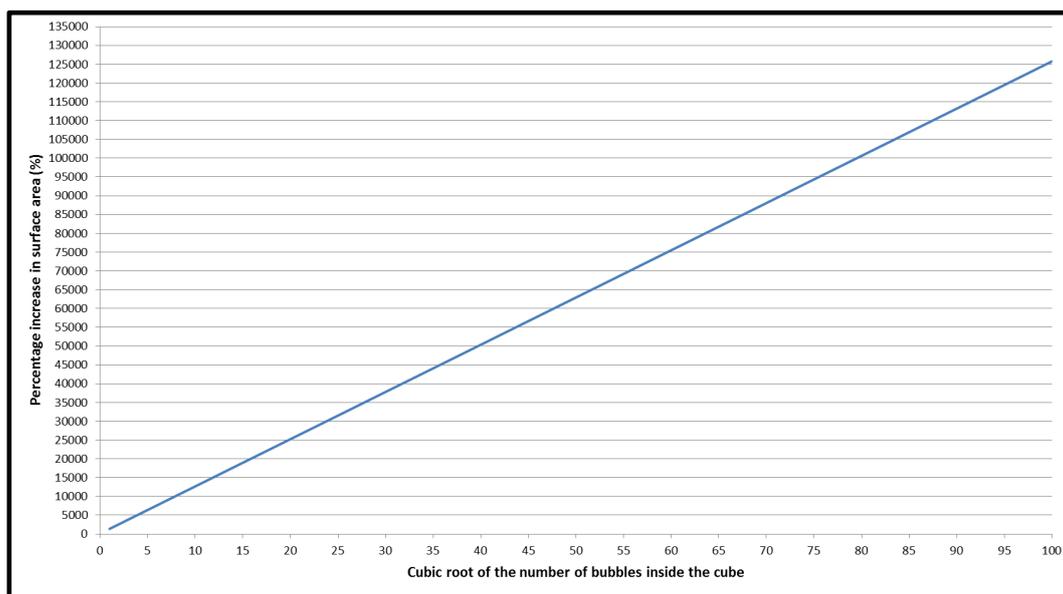

113
$$\% \text{ surface area increase due to aeration} = 1 + x^3 4\pi \left(\frac{1}{x}\right)^2 \times 100$$

114 Or:

115
$$\% \text{ surface area increase due to aeration} = (1 + 4\pi x) \times 100$$

116 This equation is valid for fully packed water cubes with bubbles. As spaces among bubbles increases the error margin
117 increases. Also it is valid for bubbles of equal volume; hence, every variation in bubble size range will also increase
118 the error margin.

119 This equation can be represented graphically to get the plot in figure 2.

120

121 Figure 2: The graphical representation of the relation between the number of bubbles inside a cube and the
122 percentage increase in surface area

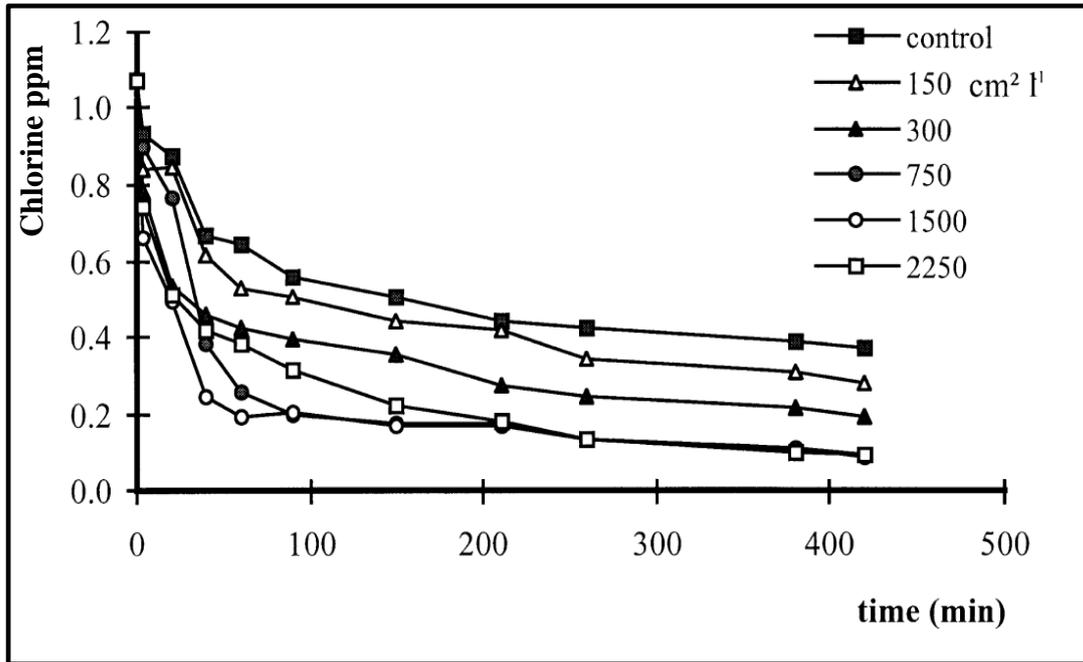

123 (Lu et al., 1999) made a set of experiments investigating the effect of the ratio of surface area to volume (S/V) of
124 chlorinated water on chlorine decay. They suggested that a 1500% increase in surface area will reduce chlorine level
125 to a value of approximately one fifth of its original level. These tests as well as the conclusion in figure 2 encourage
126 the use of air bubbling for dechlorination.

127 2.2 The role of aeration in increasing concentration gradient

128 When a fresh air bubble rises through chlorinated water, the chlorine is transferred from water to air bubble driven by
129 concentration gradient (dC). The bubble at the surface of the sparger has the least chlorine concentration, hence greater
130 concentration gradient.

131 The average velocity of a rising bubble in water column is approximately (20-30) cm/sec (Sharifullin and Luebbert,
 132 2001;Chen, 2004). Therefore, the chlorine will not have that time to reach saturation in the bubble then the
 133 concentration gradient continues to be in its maxima. The more bubble velocity the more concentration gradient.

134

135

Figure 3: Effect of surface area to volume on chlorine mass transfer rate. (Lu et al., 1998)

136 **2.3 Effect of turbulence**

137 The relation between Reynolds number, boundary layer thickness and mass transfer rate were intensively outlined. At
 138 higher Reynolds number boundary layer thickness increases, hence lower resistance to mass transfer. The higher
 139 decrease in mass transfer resistance occurs when Reynolds number jump from laminar to turbulent flow regime.
 140 Therefore, many mass and heat transfer applications that need high transferability designed to aim for turbulent
 141 Reynolds number such as car radiators and air conditioners (Incropera and Dewitt, 2007;Bird et al., 2007).
 142 Neglecting the jet effect and turbulence resulting from air effluent the sparger, for an air bubble rising in a column by
 143 buoyancy only, Reynolds number can be expressed as (Scheidt et al., 1999):

144
$$Re_b = \frac{\rho_L u_b d_b}{\mu_L}$$

145 Where:

146 Re_b : is Reynolds number for a bubble rising in a liquid (dimensionless).

147 ρ_L : is the liquid density (kg/m^3).

148 d_b : is the diameter of bubble (m).

149 μ_L : liquid viscosity ($Pa.s$).

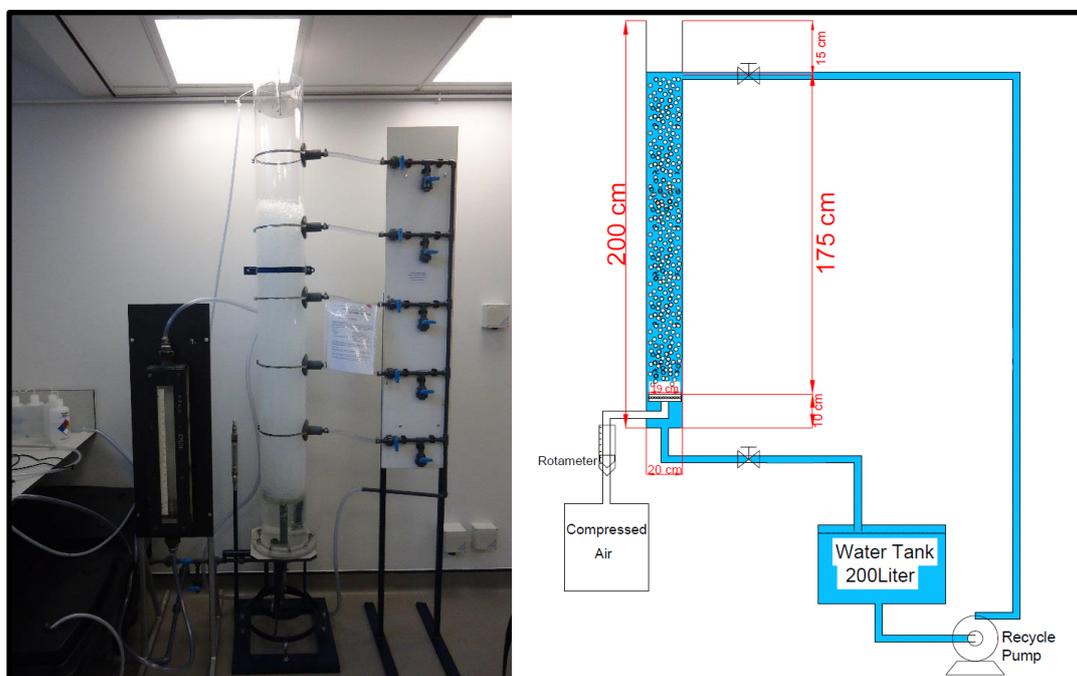

150 Values of Re_b over 500 are considered as turbulent (Lau et al., 2012). Assuming the average bubble size along the
 151 column is 1 cm and the average velocity is 25 cm/s, Re_b gives the value of 2500. With this Reynolds number there is

152 a big leap in chlorine transfer from water to bubble when using forced aeration instead of conventional stagnant
153 aeration.

154 3. Materials and methods

155 3.1 Aeration system

156

157 Figure 4: Experimental set up

158 A compact aeration column system consists of 1 m long was designed and built. The main part is a transparent Perspex
159 (Poly (methyl methacrylate)) tube, 20 cm inside diameter. A ceramic sparger, 19 cm diameter, with 50 microns' holes
160 size is fixed 10 cm above the column base. The sparger is joined to a 15 mm diameter tube connected to a compressor
161 with a rotameter (10-900 l/min) or (0-10 l/min) depending on run demands. A 200-liter tank is installed beside the
162 system to collect distilled water from a still and provide a reservoir to the column. The working capacity of column is
163 approximately 50 liters and 63 liters when totally filled. The assembly is fixed on a steel rig (Figure 4).

164 3.2 The Chlorine

165 Three chlorine sources were used in this work:

166 1- Trichloroisocyanuric acid tablets obtained from Acti.

167 2- Sodium hypochlorite obtained from SIGMA-ALDRICH (assay of 10%).

168 3- Chlorine gas: This is synthesized in the lab through reaction between trichloroisocyanuric acid and hydrochloric
169 acid (37 M); obtained from SIGMA-ALDRICH, according the following equation:

171 The produced chlorine gas is dissolved in distilled water using the system in figure 5. A peristaltic pump (Watson
172 Marlow, Model - 505S, range 2 - 220 rpm) was used for transferring chlorine gas from the reaction bottle to saturation
173 bottle then circulating it back to the first bottle.

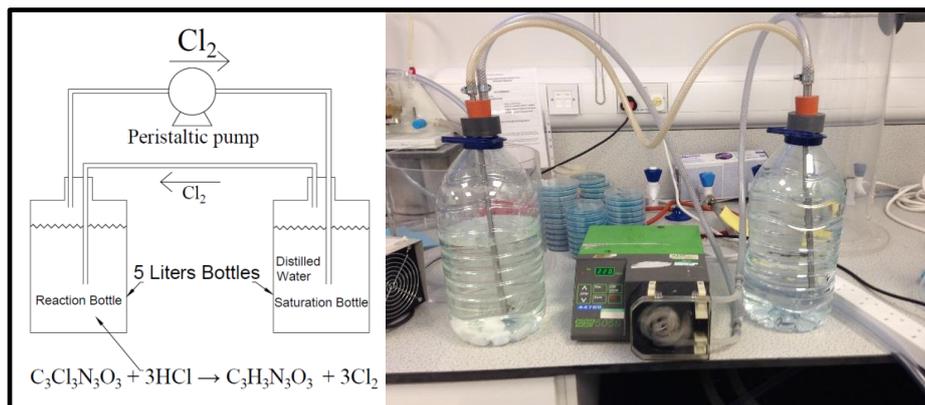

174 The reaction is implemented under standard atmospheric conditions. 100 grams of trichloroisocyanuric acid tablets
 175 were placed in the reaction bottle then 5 liters of distilled water were added. Then 20 ml HCl was added to the
 176 mixture and left till the water turns yellow. Using more or less amounts of the chemicals is not dangerous as the
 177 reaction is not fast especially with the presence of this relatively large water amount. Finally, the peristaltic pump is
 178 started to transfer the released chlorine gas from reaction bottle to saturation bottle. The increase in chlorine
 179 concentration in the saturation bottle can be estimated roughly by yellowish water, it is recommended to take samples
 180 every short period of time (say 10 minutes) for analysis until the desired concentration is reached.

181 3.3 Chlorine meter

182

183 Two chlorine meters were used in this study. The first was exact[®]Z Obtained from Industrial Test Systems, Inc. (ITS).
 184 The second was ExStik[®] obtained from EXTECH instruments, model number of CL200. Both meters are self-
 185 calibrated. In addition of that they are provided with standards for external calibration.

186

187

188

Figure 5: Chlorine production and water chlorination system

189 3.4 pH meter

190

191 The pH meter used in this work obtained from AZ[®] with the model number of 8685. The device was calibrated using
 192 three pH standard buffer solutions of the values of 4.0, 7.0 and 10 obtained from VWR international and
 manufactured by MERCK MILLIPORE.

193 3.5 Experimental procedure

194

195

196

197

198

199

200

201

- 1- Prepare 5 liters of 2000 ppm chlorine water solution in a separated bottle.
- 2- Fill the column with 45 liters of distilled water.
- 3- Add saturated chlorine solution obtained from step 1 gradually to the column with mixing to get 200 ppm.
- 4- Start air pumping at 1 l/min.
- 5- Start taking samples every 1 minute for low range or 2 minute for high range, for 30 minutes for analysis.
- 6- Stop air pumping and drain the system.
- 7- Repeat steps 1 through 6 for every new air flowrate.
- 8-

202 4. Results

203

204

205

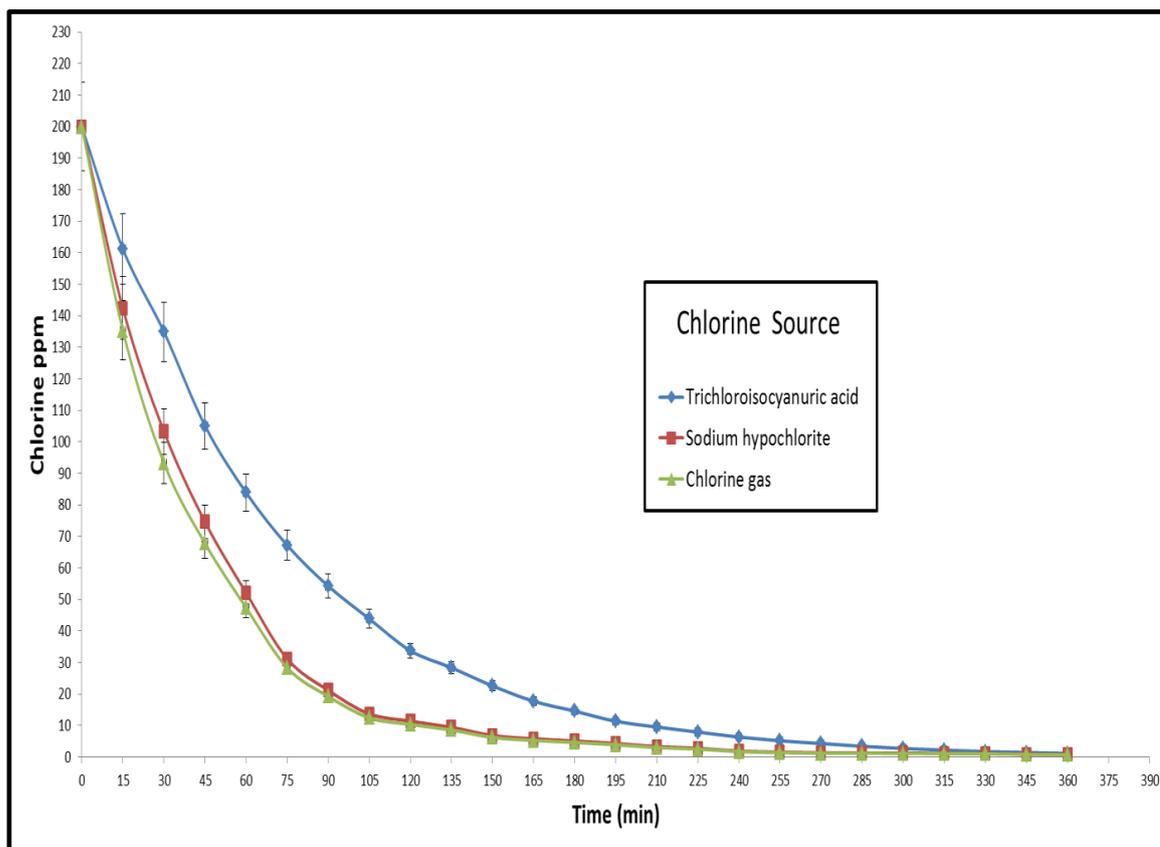

Results were expressed by measuring chlorine decay in ppm as a response of pumping time in minutes and air flowrate
 in l/min. Two ranges of air flowrates were investigated; the first was a high range (10 – 50) l/min with an interval of
 10 l/min while the second was (1-9) l/min with an interval of 1 l/min which represented the fine tune of the first range.

206 4.1 Chlorine decay without air pumping (control)

207

208

For the control chlorinated water was put in the column with the same concentration used in the full experiments and
 left to evaporate naturally. The obtained results are summarized in figure 6.

209

210

Figure 6: Natural stagnant aeration rate (control)

211

4.2 De-chlorination of chlorine obtained from trichloroisocyanuric acid

212

In this set the saturated chlorine solution in step 1 in 3.5 was prepared using trichloroisocyanuric acid (200 ppm). The

213

obtained results are summarized in figures 7 for low and 8 for high ranges of air flowrates.

214

215

4.3 De-chlorination of chlorine obtained from Sodium hypochlorite

216

In these experiments the saturated chlorine solution in step 1 in 3.5 was prepared using sodium hypochlorite (200

217

ppm). The results are summarized in figures 9 for low and 10 for high air flowrates.

218

4.4 De-chlorination of chlorine obtained from Chlorine gas

219

In this set the saturated chlorine solution in step 1 in 3.5 was prepared using chlorine gas prepared using the system

220

in figure 5 and following step 3 in 3.2 (200 ppm). The obtained results are summarized in figures 11 for low range

221

and 12 for high air flowrates.

222

4.5 Effect of air flow rate on mass transfer coefficient (Ka)

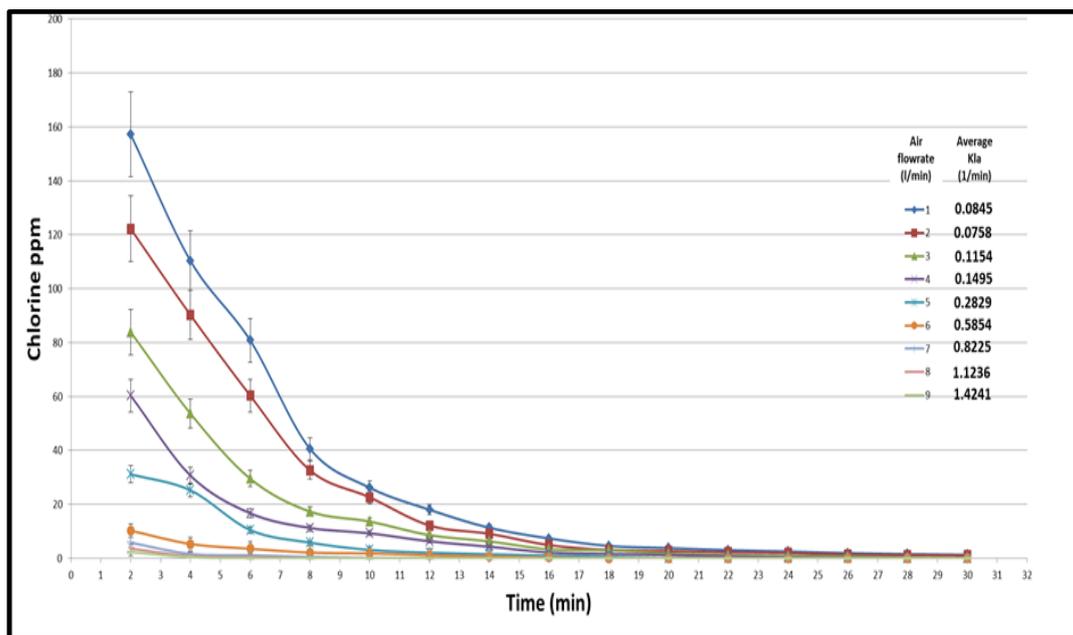

223

The average values of Kla are plotted against air flow rate. Figures 13 for low and 14 for high flowrates summarize

224

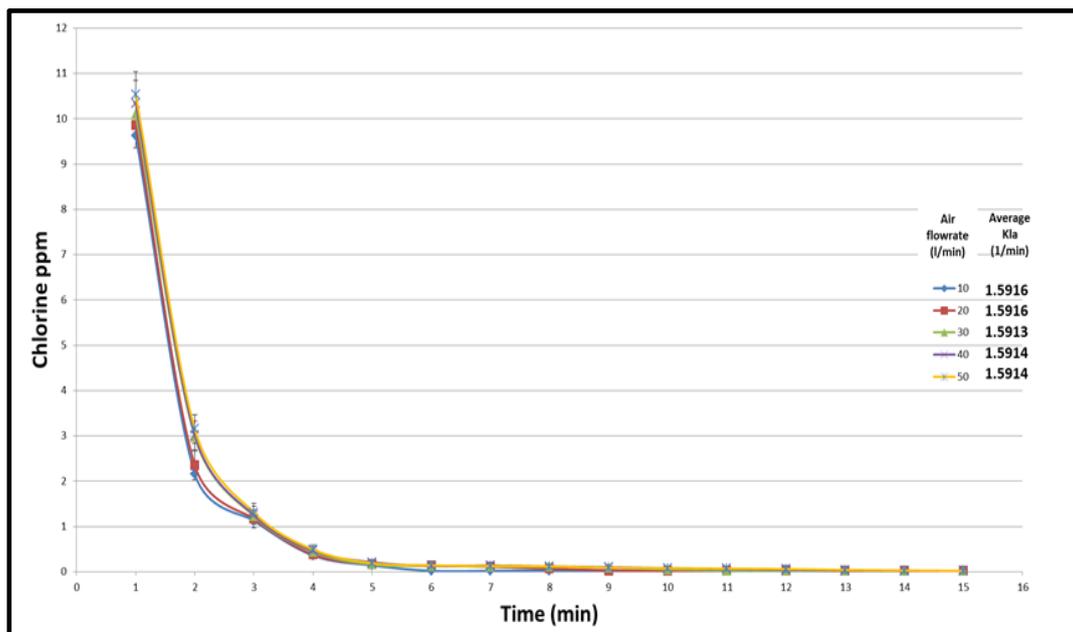

the results.

4.6 Effect of chlorination on water pH

Along all the experiments of the three chlorine sources, pH was monitored to give the results in figure 15.

246

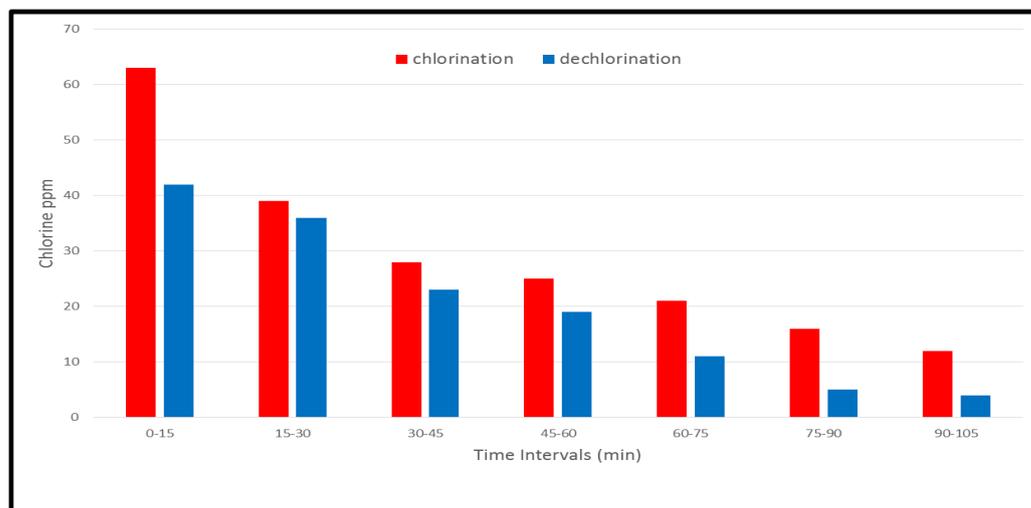

247

Figure 15: pH variation in shock chlorination for the three chlorine sources

248 **4.7 Shock chlorination rate**

249 Results are expressed as ppm reduction for dechlorination and ppm increase for chlorination during the same time
 250 intervals. Every bar is the net difference between one reading and the next one.

251 To make a fair comparison, the chlorination values near to zero ppm are compared with the dechlorination values near
 252 200 ppm because at these two values the driving forces are at their maxima. Figure 16 shows the results. It is shown
 253 that the chlorination is faster than dechlorination rate by an average of 25%.

254

255

Figure 16: Comparison between chlorination and dechlorination rates

256

257 5. Discussion

258 The main aim of this study was to investigate increasing the release of dissolved Chlorine from water by increasing
259 the mass transfer area, concentration gradient and turbulence using aeration. This hypothesis is supported and data for
260 such a process is given.

261 Chlorine is widely used in water industry. Changing this technique would cost a lot (Fawell, 2014; Powell, 2010).
262 Therefore, it is better to keep using disinfection by chlorination and trying to avoid the disadvantages.

263 The perfect drinking water system should be, free of biological contaminants and free of chemicals, especially
264 biocides. The results show that shock chlorination and shock dechlorination by aeration can produce such water. The
265 proposed purification process aims to kill the entire microorganism load with a high dose of chlorine then removing
266 this chlorine by aeration.

267 The findings of this study pave the road for using shock chlorination followed by shock dechlorination for producing
268 high quality drinking water. Dissolved chlorine can easily be removed from water by forced aeration as it provides
269 three advantages on stagnant aeration. First is the significant increase in mass transfer area as shown in figure 2.
270 Second is the increase in mass transfer boundary layer turbulence between air bubble and bulk water. The third is the
271 increase in mass transfer concentration gradient along water-bubble interface.

272 In this study, three sources of chlorine were examined for their response to dechlorination by aeration. The first was
273 trichloroisocyanuric acid which is used frequently in swimming pools due to its reaction with water to produce
274 cyanuric acid which is considered as a chlorine stabilizer that prevent chlorine from volatilizing that may result from
275 high surface area with respect to water mass in swimming pools (Harnvajanawong et al., 2004). The second is sodium
276 hypochlorite (bleach). It is the most used chlorine source in all applications as a result of its abundance, cheapness
277 and ease of use. The third was chlorine gas.

278 With all three chlorine sources the general trend is relatively fast chlorine removal from water but they do differ
279 slightly in removal rate, the final steady concentration and how fast they reach this steady concentration. For
280 trichloroisocyanuric acid the chlorine removal was optimum at 9 l/min of air and needed 6 minutes to reach the
281 minimum steady concentration. For the low flowrate range the results obeyed the hypothesis that assumes more air
282 pumping lead to faster chlorine removal. For the high range over 10 l/min the removal rate did not increase as a
283 response to air flowrate increase. This because of “the column effect”; that is, in a column, at high air flow rates there
284 will be a bubble “traffic jam” along the water column and bubbles increase in size as they rise. These two factors
285 drive bubbles to be adjacent to each other reducing the total surface area for mass transfer as well as losing the
286 turbulence along the bubble-water interface. Therefore, at higher air flowrates further increasing air flowrate had two
287 counteractive effects; first, is increasing the three driving forces of aeration “increasing surface area, increasing
288 turbulence, and increasing concentration gradient” while the opposite is “the column effect”. The more the air flowrate,
289 the more the domination of column effect and the less chlorine transfer.

290 It was concluded that in an air-water bubbling system the column effect should not start effectively before 50 l/min
291 (Hassan and Edyvean, 2015) but in this work it started after 10 l/min. This is because the relatively high concentrations
292 of trichloroisocyanuric acid and sodium hypochlorite seem to work as frothers which stimulate the column effect at
293 lower air flow

294 It was also noticed that in aerating trichloroisocyanuric acid the chlorine removal is lower when compared with sodium
295 hypochlorite and chlorine gas. Furthermore, the chlorine concentration did not reach zero even with a long aeration
296 time and stuck on 0.02 ppm. This because of the stabilizing effect of cyanuric acid that is produced from the reaction
297 of trichloroisocyanuric acid and water (Harnvajanawong et al., 2004).

298 Using trichloroisocyanuric acid in shock chlorination would give many problems and limitations. Concentration of
299 cyanuric acid, formed when trichloroisocyanuric acid is added to water, above 30 ppm leads to a phenomenon called
300 “chlorine lock” in which cyanuric acid locks the ability of chlorine to kill bacteria. hypochlorous acid is another
301 product from trichloroisocyanuric acid and water which decreases the pH to a level unacceptable for drinking water
302 (Harnvajanawong et al., 2004).

303 For the sodium hypochlorite solution, the dechlorination was faster than trichloroisocyanuric acid rather than the
 304 ability for reaching zero chlorine level. It seems that the acidic pH; not the presence of cyanuric acid alone hinders the
 305 dechlorination.

306 Shock chlorination using trichloroisocyanuric acid and sodium hypochlorite is known in the treatment of swimming
 307 pools and domestic wells. Using either of them is not a recommended practice in drinking water production for many
 308 reasons. First, is because of corrosion, especially when the construction material is cast iron. Second, is the difficulty
 309 of lowering chlorine level across the distribution system naturally. Third, there will be reaction residuals lead to a
 310 significant unacceptable effect on water pH away from the neutral value of 7. Therefore, using chlorine gas is the
 311 recommended method for shock chlorination and shock dechlorination because there will be no residual chemicals
 312 after the dechlorination.

313 Chlorination by chlorine gas is usually implemented by injecting it through water pipes. For shock chlorination this is
 314 not enough even though chlorination with chlorine gas is known to be fast. Also, releasing high doses of chlorine to
 315 the air through the shock dechlorination process implies a high health risk on the people that may live near water
 316 treatment facilities. Therefore, a new design for recycling chlorine in shock chlorination equipment is needed. Figure
 317 5 gives a preliminary idea for such design.

318 Chlorine is very corrosive substance; so it should be fully controlled to prevent the decay of the distribution system.
 319 On the other hand, Chlorine level in treatment and distribution facilities should be kept acceptable. Mostly, water
 320 distribution systems are made of three well-known construction materials; cast iron, concrete, and plastic. For cast
 321 iron chlorine is not recommended. Concrete and plastic are less affected by corrosion (Al-Jasser, 2007). Therefore,
 322 minimizing the chlorine level in water distribution system is another advantage for dechlorination.

323 Using bubble aeration has the advantage over stagnant aeration due to three physical phenomena. First is higher mass
 324 transfer area. The second is higher Reynolds number through the mass transfer interface, the third is a higher mass
 325 transfer concentration gradient; that is, the bubble is rising fast through the water column which leads to shorter time
 326 to mass transfer then there is a higher concentration gradient. Smaller bubbles have larger mass transfer area; less
 327 Reynolds number and less concentration gradient as they climb up slowly through the water column which makes
 328 them to collect more chlorine inside hence there is less concentration difference between the bubble and the bulk
 329 water. However, the comparison between small or large bubbles is a tradeoff and needs further investigation.

330 pH was monitored against chlorine removal for each chlorine source. For trichloroisocyanuric acid at 200 ppm chlorine
 331 the pH was acidic at 5.76. as chlorine was withdrawn by aeration the pH decreased till reaching 7.13 at 1.32 ppm
 332 chlorine. For sodium hypochlorite at 200 ppm the pH was 7.97 then went down 7.5 at final chlorine concentration of
 333 0.68 ppm. For chlorine gas at 200 ppm pH was 7.58 then dropped down to 7.05 when the chlorine concentration
 334 became 0.17. The reason behind these trends is that the continuous withdrawal of chlorine from the system leads to
 335 continuous withdrawal of hypochlorous acid; hence, decreasing the acidity of the water.

336 The pH results give important limitations that should be considered when selecting a shock chlorinator. Using
 337 trichloroisocyanuric acid will produce high residual of cyanuric acid which raises water acidity to unacceptable levels.
 338 The same is for sodium hypochlorite but is less marked and in basic direction. Sodium is also a side product of water
 339 dechlorination by sodium hypochlorite but its health effect is not that dangerous as stoichiometrically the produced
 340 sodium when using 200 ppm sodium hydroxide is approximately 131 ppm. Sodium is an essential component in
 341 mineral water, so this sodium concentration may still acceptable. Chlorine gas is the best for use in such application
 342 as its chlorination and dechlorination is nearly completely reversible.

343 Practically, when low chlorine concentration is needed for shock chlorination; say less than 30 ppm, the preferred
 344 chlorinator is sodium hypochlorite because of its affordable effect on water pH. For higher chlorine levels chlorine
 345 gas would be recommended but with some modifications in chlorination facilities.

346 Mass transfer coefficient is a direct reflection to the chlorine depletion rate in water. The faster the decrease of chlorine
 347 ppm the greater the mass transfer coefficient is. When plotting the term $\ln \frac{(C^* - C)}{(C^* - C_0)}$ against the time, the slope represents
 348 the value of $K_L a$. The sign of $K_L a$ was negative in all points which indicate that the process represents dissolved gas
 349 depletion from water to gas bubble.

350 K_1a values are necessary for design purposes. Therefore, they should approach the reality not the values predicted by
 351 mathematics. That is, the first few points have fast chlorine decrease hence more vertical slopes while the many others
 352 have slow decrease hence more horizontal slopes. When taking the average of these slopes, the average will show
 353 horizontality which is much away from design reality and will cause an unfair or magnified equipment. To deal with
 354 that, the average slope for the range from 200 ppm to nearly 1 ppm was taken into account as this range represents the
 355 most reliable chlorine depletion rate. Within this range equipment will be designed well and economically.

356 It is clearly noticed that K_1a values are very high at higher air flowrates. This is a direct result of the increase of mass
 357 transfer area that resulting from higher number of bubbles per certain time period and water volume.

358 K_1a values for low range air flowrates (1-9 l/min) shows an increase with respect to air flowrate for all the three
 359 chlorine sources. This is due to the parallel increase in mass transfer area that resulting from the increase of bubbles
 360 per unit volume and time. After that, when reaching 10 l/min bubbles come to be crowded inside the column and; in
 361 majority of cases, attached to each other. This attachment reducing the overall mass transfer area as bubbles will not
 362 be longer exposed to water. Over the range of 10 to 50 l/min K_1a shows nearly constant values because there will be a
 363 counteractive effect between increasing the air flowrate and decreasing the mass transfer area resulting from bubble
 364 crowd.

365 The variation of K_1a ($K_1 \times a$) or (mass transfer coefficient multiplied by the mass transfer area), is a direct result of
 366 varying the mass transfer area alone. K_1 is nearly constant at the same other variables such as pressure and temperature.

367 Every value in figures 13 and 14 is the mean of many K_1a values with respect to chlorine concentration. K_1a increases
 368 as the starting chlorine concentration increases. This because the term $(C^* - C)$; the transferred moles, is increasing
 369 also.

370 It is clear that chlorination is faster than dechlorination by an average of 25 %. The explanation behind this can be
 371 illustrated by the comparison between chlorine and air bubbles rising in water. When a chlorine bubble rises in water
 372 column, the gas that transfers across the bubble-water interface is only the chlorine. On the other hand, when an air
 373 bubble is rising along the water column, the transferred gasses across the interface are chlorine and water vapor.

374 The solubility of a gas in liquid and the counter action of the release of a gas from the liquid under the same conditions
 375 is governed by mass transfer rate. This depends mainly on the concentration gradient. In the chlorination process the
 376 concentration gradient continues to be the maximum level from the bottom to the top of the column while in
 377 dechlorination it starts at the maxima and decreases as it rises up. However, in chlorination the lower the concentration
 378 of chlorine in water the higher the chlorine transfer rate as a result of higher concentration gradient while for
 379 dechlorination process the higher the concentration in the water the higher the transfer rate for the same reason.

380 The findings of this set assumes that as the chlorination is faster than dechlorination by a factor of 25%, hence, the
 381 "air/water demand per ppm of chlorine reduction" should be reduced by the same percentage.

382 After chlorination the chlorinated water should reside in the column for a short time to kill the bacteria. Approximate
 383 calculations indicate that, at a chlorine level of 200 ppm, the contact time should be about 11 seconds (Wagnet et al.,
 384 2005). These calculations are proposed to work under moderate or low bacterial load and chlorine concentrations.
 385 Generalizing these figures for high chlorine levels is not fully recommended but can give a preliminary indication.
 386 Furthermore, such calculations are not for a complete kill of all the microorganisms but for a reduction to certain
 387 cfu/ml according to industrial bio-purification demands. Therefore, in designing a chlorination unit both chlorination
 388 and contact time have to be addressed.

389 For the low chlorine concentrations that are conventionally used in treatment processes, the dissolution time is not
 390 important as it takes little time to rise from zero to 4 ppm. However, for shock chlorination, chlorine has to rise from
 391 zero to 200 ppm. This time should be kept in mind in design calculations.

392 For design purposes, the chlorination unit dimensions can be assumed to be the same as dechlorination. This
 393 assumption depends on the fact that if dechlorination takes 2 minutes, the chlorination should take one minute and 30
 394 seconds (dechlorination takes 25% more the time of chlorination) this gives 30 seconds to kill all the bacteria. If more
 395 time is needed to do so, it should be taken into account.

396 **6. Conclusions**

397 Forced aeration is a promising technique that can be used for removing chlorine in a fast and safe way in drinking
 398 water industry. This would enable shock chlorination followed by shock dechlorination to produce microorganism
 399 and biocide free drinking water. Chlorine gas was found to be the fastest and cleanest chlorine source to response to
 400 dechlorination by aeration followed by sodium hypochlorite and trichloroisosyanuric acid respectively.

401 On average, chlorination is faster than dechlorination by 25%. This gives a good tolerance and enough idea about the
 402 dimensions of a chlorination unit. The design of a chlorination unit is not that different from a dechlorination unit. As
 403 a rule of thumb, they can be the same.
